ABSTRACT: Volcano-sedimentary serie is situated in peripheral parts of ophiolites of the mirdita zone. It is normally set above the Triassic- Jurassic carbonaceous basement and is tectonically covered by the ultrabasic massifs of the ophiolitic complex.

ÖZ: Volkano-sedimanter seri "Mirdita" kuşağındaki ofiyolitlerin kabığında yer almaktadır. Bu, düzenli biçimde organik Trias-Jura üstünde yer almaktır olup ofiyolitik kompleksin ultrabazik masifleri ile tektonik olarak örtülülmüşlerdir.

INTRODUCTION

The following two main structural units are distinguished in the geological structure of Albanides: Outer Albanides and Inner Albanides. Mirdita, Gashi and Korabi tectonic zones belong to inner Albanides. The Mirdita zone, with wide extention of ophiolites, is the main ore-bearing zone of Albania (Geology of Albania, 1982).

This paper treats the problems of the age, spatial position and the construction of Jurassic volcano-sedimentary serie, which is encountered in the peripheral parts of ophiolites of the Mirdita zone (figue. 1.)

The Jurassic volcano-sedimentary serie is almost everywhere limited by the rocks of the Triassic-Jurassic carbonaceous serie on one flank (its basement) and by the ultrabasic rocks of the ophiolitic complex on the other (its cover).

Basement of Volcano-Sedimentary Serie

Complete section which build up the basement of Jurassic volcano-sedimentary serie are developed in the eastern flank of the Mirdita zone (Kodra, A. etc. 1980; Gjata Th., etc., 1987 franbotton to top wedistin guish (Fig.2).

-Paleozoic schists.

-Conglomerates-Sandstones of Permian -Verfenian.

- Volcano-sedimentary rocks of Verfenian. The volcanics consist of olivinic diabases, porphyry diabases, andesites, dacites up to liparites. Petrochemically, the rocks belong to basic-acid serie and are highly alcalinic.

- Sandstone, sandy limestones and dolomites of Verfenian- Anisian.

- Radiolarites and limestones with cherts of Anisian and Ladinian. The phenomena of the Anisian volcanism and the Ladinian tuffs exist also at some sectors.

- Stromatolitic limestones with megalodonts and Lithiotis (shallow sea facies) and the limestones with cherats (deep sea facies) of the Upper Triassic-Lower Liassic.

- Condensed Jurassic reddish limestones (2-20 m thick) with manganese nodules. The microfacies with Involutina liassica, embryonic ammonites, Protoglobigerina, Cadosina etc. is characteristic (Kodra, A., Gjata, K., Pirdeni, A., 1979; Shallo, M. etc., 1980; Shallo, M. etc., 1986).

Volcano-Sedimentary Serie

The sequences of volcano-sedimentary serie are most complicated, with facial variations both, in extention and verticality. In spite of that, several lithological packs, well correlated in the field can be distinguished

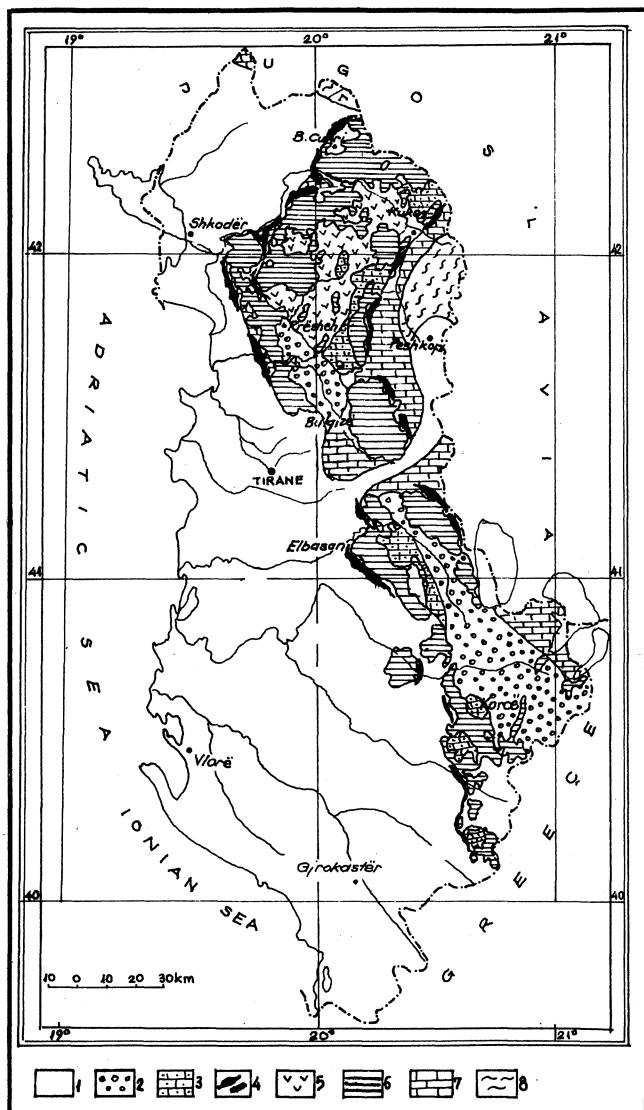

Figure 1. The Distribution of Jurassic Volcano-Sedimentary Serie in Inner Albanides.

1. Outer Albanides; 2-8. Inner Albanides; 2. Tertiary molasses; 3. Cretaceous limestones; 4. Volcano-Sedimentary serie; 5. Ophiolitic gabbro-plagiogranite-volcanic rocks. 6. Serpentinitised ultramafics; 7. Triassic-Jurassic limestones; 8. Paleozoic schists.

among this serie. The good sections of volcano-sedimentary serie, with well preserved relations regarding limestone rocks of the basement as well as the ultrabasic ones, which cover them tectonically occur in several sectors such as Fushë Lurë (figure 3) (Kodra, Al, 1981; Kodra, Al, Peza, L. H., etc., 1986), Poravë (figure 4) (Kodra, A., Delaj, E., 1976; Bezhani, V., etc., 1986; Çakalli, P., etc. 1983).

Most foreign students have investigated Dinarides and Hellenides (Cadet, J.P., etc., 1980, etc.) are of the

same opinion as regards such a setting of volcano-sedimentary serie. It is supported also by the geophysical data (Langora, LI., etc., 1983).

JURASSIC VOLCANO-SEDIMENTARY SERIE

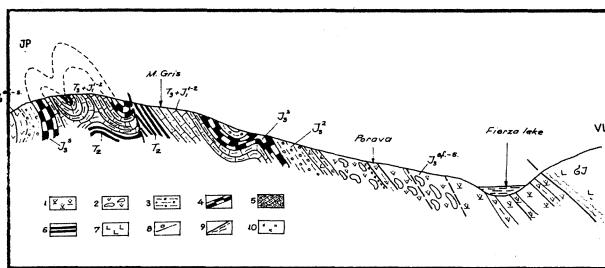

Figure 4. Coupe Géologique de Poravé
 1-4. Volcano-sédimentaires série du Jurassique supérieur; 5. Diabases et schistes métamorphisés. 2. Diabases à pillow lava et schistes siliceux; 3. Schistes détritiques; 4. Ban de Silice du Trias supérieur-Lias; 6. Schistes siliceux du Trias moyenne; 7. Harzburgites; 8. Disjunction tectonique; 9. Plan d'obduction; 10. Picrite.

Five different packs can be distinguished within volcanosedimentary serie:

a. Radiolaritic-tuffaceous pack (10-25 m). It is most characteristic and situated almost on top of Triassic-Jurassic carbonaceous serie (successively or with hard grounds) (Kodra, A., 1976, 1986).

b. Schistous pack with debris (20-150 m). It is represented by a chaotic formation (mélange). The sandstone, chert, limestone triassic volcanics and ophiocalcites are found in the argillitic matrix. The radiolaritic intercalations or the lenses of arkosic sandstone have been encountered in most cases as well.

In some sections occur also the intercalations of the basic and intermediate-alcaline (halotrichyliparites, trachytes etc.) volcanics.

c. Diabase-schistous pack (10-30 m). It consist of diabasic intercalations within schists.

d. Diabase-chert pack (50-500 m). It has a wide extension and occupies the largest volume of volcano-sedimentary serie.

The volcanics consist of diabases, albitic diabases, diabase porphyres, diabasic agglomeratic lavas etc. Of the most interest is the presence of the olivinic gabbro-diabases and picrites in the chert-diabase sequence of Poravé etc.

e. Diabasic pack with chert intercalations and schists with clasts (20-50 m). The packs c, d, e may be included in an individual pack - the diabase-chert one.

f. Metamorphic pack (20-100 m). This pack occurs everywhere at the uppermost part of volcano-sedimentary serie. The study of this pack has been conducted by Shallo, M. (1970), who distinguishes the metamorphic rocks of green schist facies as well as the metamorphic rocks of staurolite-almandine subfacies and quartz-albite epidote almandine. The formation of metamorphic rocks is linked with the

palaeomovement of ophiolites on the volcano-sedimentary basement in the end of Upper Jurassic.

In different levels (mainly in the lower ones) of volcano-sedimentary serie are located the ultrabasic (picritic) lavas, ultrabasic bodies, gabbros and gabbromonzonites etc., penetrated by undercrust (Kodra, A., Gjata, K., 1982; Gjata, K., etc. 1985 etc.).

The volcanics of volcano-sedimentary serie show a differentiated petrochemical evolution: from subalculfine basalts to basalt andesites and up to dacites «thyolito» (Ndojaj, L. 1982).

The Cover of the Volcano-Sedimentary Serie

The ultrabasic rocks of the Ophiolitic complex of the Mirdita zone lie on the metamorphic pack of the top of volcano-sedimentary serie. Their contact represents a major tectonic and is expressed by the formation of amphibolites and foliated serpentinites (of tens metres thickness). The lowermost levels of ultrabasic tectonites composed of herzolites and fresh harzburgites occur, in general, at the contact with the volcano-sedimentary serie (Kodra, A., 1976; Gjata, K., Kodra, A., 1982 etc.).

The emplacement of the rocks of the ophiolitic complex on the volcano-sedimentary serie occur during the Tithonian and is linked with the immersion of the continental crust under the oceanic one during the period of compression which closes the marginal ocean basin during the Jurassic.

The Upper Tithonian-Berriasian flyschoidal formations are set with break on the Triassic-Jurassic carbonaceous rocks, Jurassic volcano-sedimentary ones and on the other rocks of ophiolitic complex (Figure 5).

Age. The rocks of the volcano-sedimentary serie lie

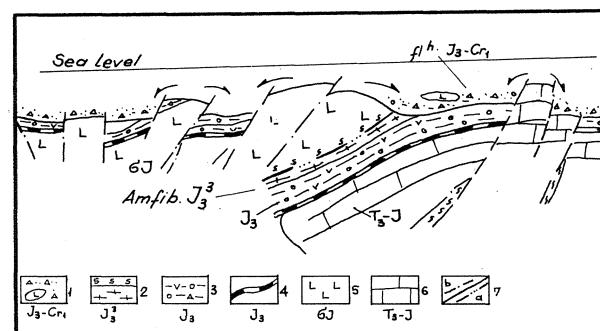

Figure 5. Relations of Early Flysch With Triassic-Jurassic Formations and Ophiolites

1. Early conglomébre-marlacéous flysch with tintinnides;
2. Amphibolites, serpentinites;
3. Argillite-détritus pack with volcanites;
4. Radiolarites-tufogénè rocks;
5. ophiolite;
6. Jurasic limestones;
7. Plain of obduction (a) and fault (b).

stratigraphically on top of the Lower-Middle Jurassic limestones and are covered by the Upper Tithonian flysch. Thus, the age of the volcano-sedimentary serie is of Upper Jurassic.

Copper mineralization. As regards Py-Cu massive mineralizations, the volcano-sedimentary serie is of the most interest. Recently, in the diabase-chert pack (fig. 2) are known two main mineralization levels. In various sectors of the spreading of volcano-sedimentary serie occur also two other levels of less important sulfide mineralization (Bezhani, V., etc., 1986; Delaj, E., 1985; Hoxha, L., etc.; 1983; Çakalli, P., etc., 1983; Avxhiu, R., etc., 1984)

CONCLUSIONS

The Jurassic volcano-sedimentary serie lies on the Triassic-Jurassic carbonaceous basement and is tectonically covered by the ultrabasic rocks of the ophiolitic complex.

In the lower part, volcano-sedimentary serie is composed of tuffaceous cherts and schists with debris (melange); in the middle part by diabase-cherts and in the upper one by amphibolites and metamorphic schiste.
